Aim of the study: Like other cancers, HCC progression is highly affected by angiogenesis and apoptosis. The present study aims to assess the potential role of the endogenous regulators of angiogenesis and apoptosis like neurotransmitters, as possible hepatocellular carcinoma (HCC) biomarkers.

Materials and methods: Five groups of rats were used in this study: a control healthy group(I) and another four intoxicated groups used for induction of HCC with a single dose of diethylnitrosamine (DENA 200 mg/kg, single I.P. dose), (II, III, IV, and V). Groups II, III, IV, and V were sacrificed following 8, 16, 24, and 32 weeks of the DENA injection respectively. Level of histamine serum samples was estimated using high performance liquid chromatography technique coupled with Diode array detector (HPLC-DAD). In addition, AFP was measured using ELISA technique.

Results: Development of HCC was confirmed by histopathological studies. The results exhibited prominent increase in serum histamine level during early and moderate stages of HCC development (group II, III, and IV) in comparison to the control, then histamine serum level declined to the normal level during last stage of HCC development (group V).

Conclusion: Histamine can be used in combination of AFP as a biomarker for detection of early stages of HCC where AFP alone has a limited detection value.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the third cause of cancer-related death and the fifth most common tumor worldwide¹. The incidence of HCC varies widely throughout the world, with rising incidence in Egypt². In Egypt, the highest prevalence of hepatitis C virus (HCV) resulted in growing incidence of HCC³, which is nearly doubled over the last decade⁴. According to results of National Cancer Registry Program (NCRP)⁵, HCC incidence rate occupied the top ranked cancer among Egyptian males and the second top rank among Egyptian females after breast cancer. The silent growth of HCC may delay the diagnosis of this disease for as long as 3 years from the time of development⁶. Early detection of HCC is the most critical step in the management process, so patients with risk factors for HCC should undergo frequent periodical laboratory investigation every 6 months to predict early development⁷. The diagnosis of HCC without pathologic confirmation can be achieved by the assessment of serum alpha-fetoprotein (AFP) level. Since its discovery in the serum of HCC patients in 1963⁸. AFP has been regarded as the most useful serum protein for HCC patients⁹. However, we still need to improve the early diagnosis of HCC because only 44% of the patients are diagnosed at a localized disease stage, and only 30% of HCC patients at the time of diagnosis are candidates for potentially curative treatments¹⁰. Thus, the discovery of an effective, reliable tool for early diagnosis of HCC to increase the number of patients who are suitable for curative treatment

will play a pivotal role in improving HCC patients’ prognosis.

Neurotransmitters act as powerful upstream regulators that orchestrate numerous cell and tissue functions, by releasing angiogenesis factors, proinflammatory cytokines, growth factors, arachidonic acid, metastasis factors, and local neurotransmitters from cancer cells and their microenvironment. Moreover, they modulate angiogenesis, proliferation, apoptosis, and metastasis of cancer directly by intracellular signaling downstream of neurotransmitter receptors.\(^{16}\)

Neurotransmitter histamine is a biogenic amine that is released throughout the entire body of an organism\(^ {17,21}\), with high concentration in the lymph nodes, stomach, and thymus, the lowest concentrations of histamine are found in the liver, brain, intestines, and lung\(^ {22}\). Histamine is an important chemical mediator that regulates different pathophysiological functions such as cellular invasion, migration, angiogenesis, differentiation, apoptosis, and different immune responses.\(^ {18}\) There have been numerous studies involving histamine in liver cancers. In a study using hepatocellular carcinoma cell lines, histamine stimulation was found to induce a differential effect by increasing the growth of one line while decreasing the growth of another. Histamine-induced effects were attenuated by inhibition of either H1 or H2 HRs.\(^ {23}\)

**MATERIALS AND METHODS**

**Animals:** Male Sprague-Dawley albino rats about 250 g were used in the present experiment. They were purchased from the animal house, Assiut University, Assiut. The animals were housed under standardized environmental conditions, fed with standard diet and left to acclimatize to the environment for one week prior to inclusion in the experiment at 22°C±2°C under a 12/12 hrs light/dark cycle. All the animal experiments were conducted in accordance with the guide for the care and use of laboratory animals of the National Institutes of Health (NIH publication No. 85-23, revised 1985).

**Chemicals:** Histamine was obtained from Santa Cruz Technology, Inc, UK (cat no. sc-202650). Diethylaminoamine (DENA) (cat. no. N0258-1E), was purchased from Sigma Chemical Company, St Louis, MO, USA. Rat Alpha-Fetoprotein (AFP) ELISA kit was obtained from WKEA MED SUPPLIES CORP, China (code no.WAR-348). Other chemicals were obtained either from Sigma Chemical Company or commercial suppliers, unless otherwise mentioned.

**Basic experimental design:** Diethylaminoamine (DENA) was used to induce HCC in rats\(^ {24,25}\) as follows: Animals were divided randomly into five groups as follows: (I) a control healthy group (injected with saline), (II, III, IV, and V) HCC induced groups (injected with DENA, 200 mg/kg single intraperitoneal dose). Groups II, III, IV, and V were sacrificed following 8, 16, 24, and 32 weeks of the DENA injection respectively. Rats were initially anesthetized with 3% halothane before they were sacrificed to collect blood and livers for experimental analyses. Blood samples were collected on the final day of the experiment after a 12 hrs fast. Blood samples were left for 15 min for *in-vitro* coagulation and then centrifuged at 3000 xg for 15 min for serum collection. Blood samples were collected for histamine and AFP measurements.

**Liver specimen preparation:** Each liver specimen was dissected into 2 pieces. One piece was fixed and embedded in paraffin block for histopathological examination, whereas the second piece was stored in liquid nitrogen (when needed), homogenized for total protein extraction. Liver specimens were fixed in 10% neutral buffered formalin for 48 hrs at room temperature. The tissues were then placed in embedding cassettes. To prepare the trimmed liver pieces for embedding in paraffin, specimens were first dehydrated gradually using increasing concentrations of ethanol in order to replace water in liver tissues. The liver tissues were then cleared by infiltrating with xylene. Finally, the specimens were infiltrated with 58-60°C liquid paraffin. Histological examination was performed on liver samples, stained with hematoxylin and eosin.
I- Measurement of serum AFP

Serum AFP was measured in serum of all animal groups using rat alpha-fetoprotein (AFP) ELISA kit (WKEA MED SUPPLIES company, China).

Principle and procedure of assay

The kit assay Rat AFP level in the sample, use Purified Rat AFP to coat microtiter plate wells, make solid-phase antibody, then add AFP to wells, Combined AFP antibody which With enzyme labeled, become antibody - antigen - enzyme-antibody complex, after washing Completely, Add substrate, substrate becomes blue color At HRP enzyme-catalyzed, reaction is terminated by the addition of a sulphuric acid solution and the color change is measured spectrophotometrically at a wavelength of 450 nm. Procedure was done following insert instructions supplied with the kit. Finally the concentration of AFP in the samples was determined by comparing the O.D. of the samples to the standard curve.

![Standard curve for AFP](image)

**Fig. 1:** Standard curve for AFP.

II- Measurement of serum histamine level

Histamine as one of biogenic amines has been traditionally determined by HPLC using diode array detector. In our study we used HPLC-DAD (Agilent Technologies 1200 series, Germany), and separation of histamine occurred on 300SB-C18 (250 mm × 4.6 mm, 5 μm) column (Merck, Darmstadt, Germany). The mobile phase of phosphate buffer (25 mM, pH 3) and acetonitrile (5:95) was run isocratic at a flow rate of 1 ml min⁻¹. Differences between the control group and the remaining groups were assessed with a 1-way analysis of variance and post hoc Student Neuman-Keuls tests using SPSS.

RESULTS AND DISCUSSION

Results

In this study we measured serum AFP as during the development of HCC, as AFP is considered the gold tumor marker for HCC. The results showed an increase in serum AFP level in all experimental groups (Groups II, III, IV, and V) in comparison to control group (Group I), but this increase was significant only during moderate and late stages of HCC development (Groups IV and V with p value= .03 and .01 respectively). Unfortunately there is no significant difference between group IV and V, so the change in AFP level can not reflect the stage of HCC. (Fig. 2, Table 1).

**Histopathological examination of hepatic tissues:** A Normal hepatic tissue showed normal cellular shape with no sinusoidal growth pattern, cellular and nuclear pleomorphism, prominent nucleoli, or increased nuclear/cytoplasmic ratio (N/C ratio) as shown in (Fig. 4-A). 8 weeks after administration of DENA (in a dose of 200 mg/kg body eight I.P.) resulted in increased nuclear/cytoplasm (N/C) ratio with high grade sinusoidal pattern (Fig. 4-B). 16 weeks after administration of DENA caused multinuclear giant cell formation with increased mitotic figures (Fig. 4-C). 24 weeks after administration of DENA showing multinuclear giant cell formation and increased width of cord cells more than two cells, and poorly differentiated HCC (Fig. 4-D). 32 weeks post DENA injection showing cellular and nuclear polcomorphism, increased width of cord cells more than two cells, with microacinar formation (Fig. 4-E).
Discussion

Although histamine was proposed since 1960 to have a probable role in carcinogenesis\textsuperscript{21}, it still remains under discussion today. Histamine can produce different and, sometimes, contradictory effects on tumor cell growth through activation of its four membrane-specific receptors, H1, H2, H3 and H4. Moreover, most of the physiological and pathological actions of histamine have been shown to strictly depend on both its endogenous/ exogenous concentration and the tumor cell type under study. H1 and H2 receptors were the first two histamine receptor subtypes described and thus, the most frequently investigated in tumor cells and tissues. Selective activation of the H1 or H2 receptor has been shown to produce, respectively, inhibition or stimulation of tumor growth in a dose-dependent manner\textsuperscript{31&32}.

Our results showed a highly significant increase in serum histamine level than the control during early stages of HCC development (Group II and III), while serum histamine level for moderate stage of HCC development (Group IV) showed significant increase than the control group and significant decrease than early stage groups (II and III), finally group V which represents the late stage of HCC development showed return of serum histamine level to normal without any significant change than the control. We can explain our results depending on the diverse effects of histamine which were found in many types of cancer, where this diverse effect owed to difference in histamine concentration, for example in induced mammary adenocarcinoma and pancreatic carcinoma, histamine in low concentrations increases tumor cell proliferation whereas higher histamine levels decreases cell proliferation via receptor activation thereby inducing a G0/G1 cell cycle arrest associated with partial stimulation of cell differentiation\textsuperscript{33&34}. Histamine can behave as a pro- or an anti-proliferative factor within the same tumor type cells, depending on its concentration and the receptor subtype to which it binds\textsuperscript{35}. Similar results have been reported for hepatocellular carcinoma cells\textsuperscript{35}. Transformation of the initiated hepatocytes into hepatocellular carcinoma is a multistage complex process, and occurs through various stages which include disease initiation, promotion and progression\textsuperscript{36}. Histopathological results for our experiment show slow rate for HCC growth during the first 16 weeks (group II &III), these two groups also show high serum histamine level, while the rapid cancer growth was in group IV&V which showed significant decrease in serum histamine level than groups II and III, so high histamine level in group II &III may be responsible for the tumor growth suppression in these groups, while low histamine level in group IV&V promotes tumor cell proliferation.

It is known that histamine is induced and readily made available in rapidly growing tissues\textsuperscript{37}. Within these tissues, intracellular histamine is released from mast cells\textsuperscript{38&39}. Histamine can also be catalyzed from L-histidine by the enzyme L histidine decarboxylase (HDC)\textsuperscript{40&41}. So we have two probable reasons for change in serum histamine level, change in HDC level and/ or change in mast cell number.

Accumulated evidence points to a direct relationship between upregulation of HDC activity and growth of several types of human tumors. Over expression of HDC at both the mRNA and protein levels and increased levels of histamine have been shown in melanoma\textsuperscript{42}, small cell lung carcinoma\textsuperscript{43}, breast carcinoma\textsuperscript{44}, endometrial cancer\textsuperscript{45} and colorectal carcinoma\textsuperscript{46}. Burtin and et al. measured HDC in patients suffering from primary liver cancer and found that change in histamine level not accompanied by any change in HDC level\textsuperscript{47}, so another explanation for change in histamine level during HCC growth is needed.

Mast Cells where histamine is stored are increased in number in association with many types of malignant tumors\textsuperscript{48-50}. HCC tissues with different histological grades showed different numbers of mast cells, with well-differentiated HCC showing the highest number. They tended to decrease in less-differentiated HCC, suggesting a possible role in the early stage of HCC development\textsuperscript{51}, so this may be the explanation for the significant increase then the decrease in serum histamine level which we recorded in our work during early and last stages of hepatocellular carcinoma development respectively.
Conclusion

Measurement of histamine serum level may have an important diagnostic value for early detection of HCC growth, and more investigation is needed to evaluate the diagnostic efficacy of histamine serum level in screening process of HCC high risk populations as those with cirrhotic liver due to viral hepatitis or alcoholism.

الهستامين كعامل جديد مساعد لتشخيص سرطان الكبد الخلوي معملياً

نيل محيي عبد الحميد | أحمد علي عبد الغني | دالية السيد شهاته

قسم الكيمياء الحيوية، كلية الصيدلة، جامعة المنها
قسم الكيمياء الحيوية، كلية الصيدلة، جامعة الأزهر (فرع اسيوط)
مستشفى صحة المرأة، جامعة اسيوط، مصر

سرطان الخلايا الكبدية هو من أكثر الأمراض السرطانية انتشارا في مصر ويرجع السبب في ذلك إلى تشخيص مرض التهاب الكبد الفيروسي سي بين المصريين بنسبة تجاوز 10% وهي من أعلى النسب العالمية. يتم تشخيص سرطان الخلايا الكبدية بشكل أساسي وروتيني عن طريق قياس مستوى الألفا فيتو بروتين في الدم إلا أن هذا الاختبار يفتقر إلى الحساسية العالية في اكتشاف المرض حيث لا تتجاوز نسبة الألفا فيتوبروتين كثيلة لسرطان الكبد أكثر من 65%، لذا نجد أننا في حاجة للبحث عن دالة أخرى تستخدم متفرقة أو بالتزامن مع الألفا فيتوبروتين للحصول على درجة حساسية عالية في اكتشاف المرض.

تلعب الناقلات العصبية دورا هاما كأحد العوامل التي تقوم بتشويط أو تثبيت نمو الخلايا السرطانية، حيث إن العديد من هذه الناقلات تؤثر تأثيرا مباشرة على العديد من العمليات الحيوية كنمو الأوعية الدموية المغذية للخلايا السرطانية وكذلك عملية الموت المبرمج للخلايا. إذا كان الهدف من هذه الدراسة هو قياس مستوى أحد هذه الناقلات خلال مراحل نمو سرطان الخلايا الكبدية وتحديد ما إذا كان هناك تغير في مستوى هذه الناقلات خلال المراحل المختلفة لنمو المرض وتحديد ما إذا كان من الممكن استخدام هذا التغير في حالة وجوده لتحديد مرحلة تطور المرض. من اهم هذه الناقلات العصبية والتي تناولت دراسات سابقة تأثيرها على سرطان الخلايا الكبدية هو الهستامين والذي يفرز من خلايا عديدة في الجسم. هناك العديد من الدراسات التي تم إجرائها لمعرفة دور الهستامين تأثيره على خلايا الكبد السرطانية وأظهرت هذه الدراسات نتائج متباينة حيث وجد أن الهستامين في التركيزات العالية يقوم بتبطيط المرض بينما في التركيزات المنخفضة يؤدي دورا عكسيا بهدف تحمي نمو خلايا الكبد السرطانية.

أظهرت نتائج هذه الدراسة زيادة مُثيرة في مستوي الهستامين بالدم في المراحل الأولى لنمو سرطان الخلايا الكبدية بالمقارنة بزيادة غير مؤثرة في مستوي الألفا فيتوبروتين خلال هذه المراحل، مما يعطي احتمالية أفضلية لاستخدام مستوي الهستامين بالدم كدالة للكشف المبكر لسرطان الخلايا الكبدية.
